Component schedule A component list can name a rectifier, battery, breakers and controller yet still leave a telecom site electrically undefined. The missing information is usually at the handoffs: what one component delivers, what the next component accepts, which device interrupts a fault, who owns a control decision and what remains powered when the normal source disappears.

Well-defined **telecom power systems** therefore need more than a bill of materials. They need a traceable relationship between the energy path, the control path and the physical environment. This article follows those relationships from the first site-energy connection to the terminals of the communications load.

The interface test. For every connection, identify the upstream output, downstream input, permitted voltage and current conditions, protective boundary, isolation method, measurement point, control authority and expected state after a fault.

What components make up a telecom power system?

A telecom power system comprises the equipment that receives available energy,

converts it into a usable electrical form, stores reserve energy, distributes protected power, supervises operating states and supports the connected ICT loads. Cabling, switching, protection, sensors, cabinet thermal control and communication interfaces belong to that system boundary when they affect whether the load receives acceptable power.

ETSI TS 102 121 V1.4.1 (2025-02) describes power supply systems by their output and distinguishes interfaces between primary power and the installation, between the power supply and distribution, and between equipment and the telecommunications network. That interface view is useful because a single factory cabinet can contain several functions, while a large site may distribute the same functions across separate panels and racks.

The component boundary should be functional before it is commercial. “Hybrid cabinet,” “power plant” or “battery system” may be valid product names, but each proposal still needs to reveal the functions inside the assembly and the connections that remain outside the supplier’s scope.

Functional group	Examples of physical components	Boundary that must be explicit
Energy entry	AC switchgear, generator changeover, PV isolation and surge protection	Source quality, connection point, available current and isolation ownership
Conversion	Rectifier, solar DC converter, DC/DC converter, inverter or UPS stage	Input window, output window, continuous duty, derating and failure response
Storage	Battery modules, BMS, contactor, current sensor and branch protection	Charge/discharge authority, usable operating window and abnormal-state isolation
DC backbone	Busbars, disconnects, distribution panels, fuses, breakers and load contactors	Current path, fault separation, conductor rating and expansion limit
Supervision	System controller, meters, sensors, I/O and communications gateway	Measurement source, alarm meaning, control priority and loss-of-communication state
Load interface	Feeder cable, terminal, local DC/DC stage and equipment input protection	Actual load voltage range, polarity, peak demand, return path and allowable interruption

Why must energy, control and thermal paths be checked together?

The three paths interact during every important site event. The energy path carries current to the load; the control path measures conditions and commands supported devices; the thermal and service path keeps components inside their qualified environment and accessible for maintenance. A design can fail even when only one of the three is incomplete.

1. **Energy path.** Follow conductors from utility, generator or renewable input through conversion, storage connection, common bus, branch protection and the load terminals. Record every point where voltage form, polarity, available current or fault contribution changes.
2. **Control and information path.** Follow measurements, BMS communications, dry contacts, controller logic, load-shed commands and remote alarms. State which local protection acts even when supervisory communication is unavailable.
3. **Thermal and service path.** Follow heat from conversion losses, batteries, solar gain and auxiliaries to the external environment. Check airflow, compartment separation, cable access, clearances and the maintenance state required to replace a component.

For example, a controller may command battery charge correctly, but undersized conductors or an active BMS limit can prevent the intended current. A rectifier shelf may have spare nameplate capacity, but restricted airflow can reduce qualified output. A load breaker may be accessible, yet upstream isolation may not support the planned maintenance procedure. The three-path review exposes those mismatches before commissioning.

Energy enters through a qualified site boundary

The energy input stage is where available sources become an acceptable input to the site’s conversion equipment. It does not make a weak grid stable or a variable PV array dispatchable by itself; it provides the switching, isolation, protection, surge-control and measurement boundary needed for the selected source arrangement.

Utility and generator inputs normally reach AC switching and protection before the rectifier or AC load. The design must identify phases, frequency and voltage conditions, source changeover arrangement, neutral and earthing treatment, fault capacity, surge exposure and the largest permitted demand during normal operation and recovery. Generator-backed designs also need an agreed start/stop and cooldown authority rather than an unexplained “generator input” terminal.

PV strings arrive through a different electrical path. Array configuration, DC isolation, surge protection, cable routing and the solar controller’s permitted input window determine whether irradiance can be converted safely into useful bus energy. The distinction between an AC/DC rectifier and a PV DC/DC controller is explained in the solar controller versus telecom rectifier guide .

Multiple sources should not be drawn as arrows that merge without ownership. The project must say whether they meet on an AC bus, a DC bus or through a hybrid conversion stage; which source establishes the output target; how reverse current is prevented where required; and what happens when one source is present but outside its

accepted range.

Which conversion components belong between the source and the DC bus?

The required conversion component depends on the electrical form presented by the source and the form accepted by the next interface. A rectifier performs AC/DC conversion, a solar controller typically performs controlled PV DC/DC conversion, another DC/DC stage can adapt or isolate one DC interface from another, and an inverter or UPS stage may be needed for an approved AC load. The project may use one or several of these functions.

A converter should be specified at both sides. On the input side, record the operating range, maximum current, source behaviour, protection and derating conditions. On the output side, record the adjustable or regulated range, continuous and transient capability, sharing behaviour, ripple or power-quality limits where applicable, and the state produced after an internal or upstream fault.

The rectifier plant often supplies live DC demand while also providing permitted battery recharge power. Its module quantity, qualified output, redundancy and distribution limits are separate decisions covered in the telecom rectifier system guide . This component article only establishes where that plant hands power to the wider site.

Conversion losses become cabinet heat and upstream energy demand. Efficiency at a single catalogue point cannot represent every source condition, load percentage or ambient temperature. Procurement should request the curves and derating data needed for the project’s operating range, then include the resulting losses in source, conductor and thermal calculations.

The storage branch moves power in both directions

A **battery storage branch** accepts controlled charge current when sufficient source power is available and supplies current when source output is unavailable or inadequate. Its functional components can include battery modules or strings, a BMS, contactors, fuses or breakers, disconnects, current and temperature sensing, interconnects and the cabinet environment around them.

The battery should not be treated as a fixed-voltage block. Charge and discharge limits can vary with chemistry, temperature, state of charge, battery condition and BMS state. The DC bus, rectifier controller and any renewable-energy controller need one defined response when the battery restricts current, opens a contactor, loses communications or

reaches a project limit.

A common parallel arrangement can allow the battery to support the DC bus when the normal source fails, but not every project uses the same topology. Some installations include switching, separate chargers, isolated converters or multiple battery branches. The released drawing and control narrative must show the actual current path rather than relying on the word “backup.” Battery chemistry, BMS behaviour and lifecycle considerations remain owned by the telecom lithium battery engineering guide .

How does the DC backbone deliver power to critical loads?

The DC backbone connects qualified sources and storage to individually protected load feeders. It includes the common bus or powerboard, main disconnects, battery connection, current measurement, distribution panels, branch protective devices, optional load contactors and the conductors and return paths that complete each circuit.

Effective **DC distribution** separates a downstream fault without creating an unacceptable loss of healthy loads. That outcome depends on available fault current, device characteristics, conductor and terminal ratings, voltage drop, load input behaviour and the coordination strategy. An empty breaker position proves physical space only; it does not prove spare bus, source, thermal or cable capacity.

Each feeder should end at a known interface. Record the load’s accepted voltage range at its terminals, polarity or conductor convention, steady and transient demand, inrush where relevant, local input protection, cable length, voltage drop and the state expected after branch isolation. A nominal bus label alone cannot establish compatibility.

The single-line drawing owns the formal representation of isolation and protection boundaries. Until the dedicated single-line guide is published, use the telecom energy standards guide together with the project’s approved electrical documents when converting this component chain into a controlled design.

A critical load is a declared operating duty

Critical DC loads are the equipment and operating states that the approved site strategy requires the power system to support. Radio and transmission equipment are obvious candidates, but controllers, monitoring, cooling, access, security or tower auxiliaries may also affect service continuity or safe recovery. Criticality must be assigned by the operator or project authority, not inferred from the equipment label.

The load schedule should separate steady demand from peak, startup and scheduled demand. It should also distinguish present equipment from committed expansion and identify internal conversion losses when a device receives one voltage and uses another.

A value copied from a nameplate can be useful for a preliminary ceiling, but measured or manufacturer-qualified operating profiles provide better evidence for the final duty model.

Load priority becomes visible during scarcity. If solar production falls, the grid fails or battery reserve reaches a controlled threshold, the site needs an approved sequence for retaining essential communications and shedding permitted auxiliaries. That sequence belongs in the control narrative and acceptance tests; it should not be improvised by selecting smaller branch breakers.

What makes a telecom power system observable?

A telecom power system becomes observable when measurements and status points reveal the state of its important sources, converters, storage branches, distribution circuits and environment—and when each alarm has an assigned meaning and response. A dashboard cannot repair missing sensors, ambiguous alarm mapping or an unmeasured branch.

Recommendation ITU-T L.1395 (07/2025) organizes monitoring and control information around infrastructure subsets including DC systems, rectifiers, batteries, AC UPS, generators, alternative power systems, sensors, cooling and ICT equipment. The exact project point list can be smaller or larger, but its hierarchy should preserve component identity.

Useful **power system monitoring** distinguishes raw measurements, calculated values, equipment states, warning alarms, protective trips and communications failures. It also records timestamp, source and unit consistently enough for operations staff to reconstruct what happened. The telecom energy monitoring KPI guide explains how selected records support availability and maintenance decisions.

Local protection remains responsible for fast equipment safety functions within its approved design. Remote control should have explicit permissions, interlocks and fallback states. If communications are lost, the site must retain a defined local operating state instead of waiting for a network command that cannot arrive.

Walk the component chain through four operating states

A static power-flow arrow proves only that components can be connected. A state walkthrough tests whether their controls, protection and capacities remain coherent when the site changes condition. The four states below expose many incomplete handoffs without pretending to replace a project hazard or fault study.

State	Expected component behaviour	Evidence to review

Normal source available	Approved sources carry live load; storage remains within its permitted charge strategy; alarms indicate normal state.	Source readings, converter loading, bus voltage at defined points, battery current and branch current
Normal source lost	Permitted reserve path supports declared loads; source-failure alarm appears; prohibited reverse or transfer paths remain blocked.	Transfer record, lowest load-terminal voltage, battery/BMS state, retained and shed load list
Source restored	Live load remains supported while recharge and source recovery stay inside approved input, converter, battery and thermal limits.	Recharge current, source demand, module loading, temperature trend and alarm clearance sequence
Component isolated	The defined maintenance or fault boundary is open; healthy components remain in their approved state; remote status matches the physical state.	Isolation indication, remaining capacity, affected branches, interlocks and return-to-service record

The recovery state is frequently more demanding than normal operation because the system may supply full communications load and recharge depleted storage at the same time. Upstream switching, conversion capacity, conductors, thermal management and source limits should be checked against that combined duty.

What should be frozen before component procurement?

Freeze a component-and-interface schedule, not only a preferred product family. The schedule should identify every functional item, its upstream and downstream connection, qualified operating range, continuous and transient duty, derating basis, protection and isolation boundary, controller relationship, monitoring points, physical location, service clearance and required verification document.

- **Source boundary:** connection data, source quality assumptions, available capacity, switching and fault information.
- **Conversion boundary:** released module and shelf configuration, input/output limits, losses, derating and supported control functions.
- **Storage boundary:** approved battery configuration, BMS protocol, current limits, protective devices and communication-loss response.
- **Distribution boundary:** bus and branch ratings, protective-device schedule, feeder data, load priority and documented expansion limit.
- **Control boundary:** point list, alarm mapping, control authority, protocol, timestamps and local fallback behaviour.
- **Physical boundary:** cabinet construction, thermal method, cable entry, bonding, environmental conditions and maintenance access.
- **Acceptance boundary:** drawings, datasheets, settings, FAT/SAT procedures, test results and as-built records required for handover.

Huijue can supply individual equipment or integrate a project-specific outdoor telecom energy platform within its telecom power products and engineering scope . The proposal should state which functions are factory integrated, which are supplied loose, which are installed by others and which project assumptions still require confirmation.

Project boundary. This explainer does not select a universal voltage, polarity, battery chemistry, protection device, redundancy level or cabinet cooling method. Final ratings and settings require the actual load interfaces, source data, environmental conditions, fault information, operator rules and applicable electrical requirements.
